In [200…

```
# Create splines
x = share_filtered["eduyears_mod"].to_numpy()
```

```
share_filtered["eduyears_mod_0_7"] = np.minimum(x, 7.0)
share_filtered["eduyears_mod_7_17"] = np.minimum(np.maximum(x - 7.0, 0.0), 17.0-7.0)
share_filtered["eduyears_mod_17"] = np.maximum(x - 17.0, 0.0)

x = share_filtered["bmi"].to_numpy()
share_filtered["bmi_0_24"] = np.minimum(x, 24.0)
share_filtered["bmi_24_56"] = np.minimum(np.maximum(x - 24.0, 0.0), 56.0-24.0)
share_filtered["bmi_56"] = np.maximum(x - 56.0, 0.0)

x = share_filtered["income_pct_w4"].to_numpy()
share_filtered["income_0_9"] = np.minimum(x, 9.0)
share_filtered["income_9"] = np.maximum(x - 9.0, 0.0)
```

I have decided to create splines for BMI, income, and years of education, as for these variables, the graphs show possible non-linearity. I have chosen to create the splines at points where the lowess curve takes a turn from being positive to negative or vice versa (ecuation, income, bmi) or in the middle of curves which have too much of a curvature (education)

2.4

In model 1, the coefficient on female is -0.097 whilst for models 2 and 3, it's -0.093 (all significant at p<0.001). For model 1, this means that females (holding all else constant) are 9.7% less likely to exercise than men. For models 2 and 3, that difference in probabilities is 9.3%.

In models 1, 2, and 3, the coefficients on age are -0.009, -0.007, and -0.008 respectively (all significant at p<0.001). This means that as one gets older by a year, their predicted chance of exercising (holding all else constant) decrease by 0.9%, 0.7%, and 0.8%, respectively per the relevant model.

In models 2 and 3, the coefficients on bmi_0_24 are 0.011 (both significant at p<0.001). This means that as one increases their BMI by 1, their predicted chance of exercising (holding all else constant) increases by 1.1%, if their BMI is between 0 (not inclusive) and 24 (inclusive). The coefficients on bmi_24_56 are -0.013 (both significant at p<0.001). This means that as one increases their BMI by 1, their predicted chance of exercising (holding all else constant) decreases by 1.3%, if their BMI is between 24 (not inclusive) and 24 (inclusive). The coefficients on bmi_56 are 0.032 and 0.029 respectively (one significant at p<0.001 and the other at p<0.01). This means that as one increases their BMI by 1, their predicted chance of exercising (holding all else constant) increases by 3.2% and 2.9% respectively, if their BMI is above 56.

2.5

It appears that men tend to exercise more (or at least declare that they do so). This could be explained by differences in declaration (men might be more prone to label more activities as exercise (such as work around the house etc.)). It could also be explained by a larger portion of men in blue collar jobs.

It is interesting to see that education does not appear to have much influence on exercising besides the spline eduyears_mod_7_17 (but even there, the effects are low even with strong significance). This might be because we don't have enough observations in the other two splines. The small effect in 7_17 might be explained that as one becomes more educated, they become more aware of the health effects of a sedentary lifestyle. Thus, some people become motivated to move at least once a week.

For BMI, the biggest surprise lies in the spline bmi_56. People with a BMI above 56 are morbidly obese, so one would imagine almost no exercise compared to people with lower BMIs. However, it might be thas as people increase their BMI in the above56 spline, their health is so bad that they become forced by their caretakers to move at least a bit to minimise the negative effects on their health.

Significance levels: * p < 0.05, ** p < 0.01, *** p < 0.001. Format of coefficient cell: Coefficient (Std. Error)

Using the splines was a correct decision. The R^2 increases slightly. We also get a glimpse into the interval of education that makes the biggest difference (between 7 and 17 years) compared to the others that are not statisticall significant.
